TIG welding machines

A feasibility study comparing two commercial TIG welding machines for deep penetration

R French, W Yeoadon, G Kapellmann-Zafra and H Marin-Reyes

This paper – from the IIW 2018 International Conference hosted by the Indonesian Welding Society on 19 and 20 July 2018 in Bali – follows observations of novel weld-pool activity during TIG welding in the 300 to 1 000 A range at the University of Sheffield.

Developing deep penetration-TIG welding to produce welds of equal quality to the industrial standard practice of laser-based welding techniques has the potential to lower production cost and complexity. The detrimental effects of the necessary higher currents required to increase penetration depth in conventional TIG welding have been shown to be circumvented through K-TIG and A-TIG techniques. However, prior experimental work on weld-pool dynamics in conventional TIG welding in higher current regions has been sparse as TIG welding enhanced through novel techniques provides the best quality welds.

This paper is an early feasibility study for deep penetration welding techniques motivated by observations made during research done at The University of Sheffield where novel activity in the weld pool was identified during TIG welding with a VBC IE500DHC at between 300 and 1 000 A. This current range is labelled the ‘Red Region’. Understanding the weld pool dynamics in the ‘Red Region’ allows the potential exploitation of novel techniques for deep penetration TIG welding. Addressing this, the paper compares the quality of welds produced between 300 A and 200 A on 316 stainless steel by two industrially loading welding machines; the Miller Dynasty 350 and the VBCIE500DHC.

Introduction

Achieving consistent high-quality deep penetration welds is a difficult but potentially highly profitable endeavor. Due to complex activity in the weld pool, deep penetration welding requires the use of specialized techniques to push the weld pool deeper into the workpiece. The prevailing industrial solutions of Laser-based deep penetration techniques are expensive and cumbersome to transport. An off-the-shelf TIG technique has the potential to drastically reduce costs and expand the applications of deep penetration welding. TIG welding does not require any preparation of the workpiece and, through novel modification of TIG welding, a technique which manipulates weld pool dynamics to achieve deep penetration could be developed.

TIG welding solutions for deep penetration require novel techniques to avoid the adverse effects of the large current required for deep penetration, such as the bead with becoming excessively lumpy. At the present, the two most successful solutions are A-TIG and K-TIG.

The active flux TIG or A-TIG technique is a good demonstration of how the Marangoni effect can be utilized to achieve deep weld penetration. The active flux TIG uses surfactants to the workpiece to increase the surface tension in the centre of the weld pool so that Marangoni convection pushes the weld pool deeper into the workpiece. Keyhole TIG or K-TIG is an industrially popular technique. The novel principle of K-TIG is to cool the weld torch by circulating water around it, which allows for a higher current to be used so that a keyhole can be formed during welding.

Research at The University of Sheffield into deep penetration welding found 300 A to be a threshold current during TIG welding. From observations with a thermal camera it was observed that at and above 300 A severe fluctuations in the weld pool began. This observation led to study into the possible causes of this activity and whether this effect could be used in the creation of a novel deep penetration technique. The welding current range of this effect is prominent from 300 A to 1 000 A. This has been labelled the ‘Red Region’.

After reviewing the literature for past standard TIG welding research at this current range, no detailed documentation of observations of this effect were found [1], [2]. A 1984 study by Lin and Edgar into the influence arc pressure has on the geometry of the weld pool found 300 A to be the current at which the surface tension and hydrostatic potential energy is overcome by the arc pressure [3].

The subsequent deep depression in the weld pool could not completely be modelled just by considering the arc pressure but could be explained with the inclusion of a compound vortex – a forced vortex in the centre of the liquid weld pool surrounded by a free vortex. In addition to this, previous K-TIG studies have found 300 A to be the threshold for the surface tension to be overcome by the arc pressure [4]. However, this is with the increased energy densities achieved with the K-TIG technique so the behaviour of the weld pool under standard TIG welding may not be identical.

This is in addition to the several input variables that determine the behaviour of the weld pool during welding and the quality of the weld produced. Factors such as the weld speed, arc gap and the material being welded may mask the physical mechanisms that result in the effects observed in the ‘Red Region’. Thus, to investigate the ‘Red Region’ an understanding of which factors are not involved is imperative.

To address this, the paper will briefly describe the effects affecting weld pool dynamics and TIG welding arc physics before reviewing prior deep penetration welding technologies. Following this, the experimental procedure of the undertaken work will be described and then the results will be presented and discussed.

Weld pool dynamics

The weld pool is highly active during welding with several competing effects resulting in complex motion of the molten metal. The main forces involved are the Marangoni effect, the Lorentz force and the Arc pressure [5]. The Marangoni effect occurs during welding as there is a gradient in surface tension in the weld pool and metals have a variation of surface tension with temperature. So, molten metal in areas of lower surface tension flows towards areas of higher surface tension. For deeper penetration, the surface tension of the centre of the weld pool at the highest surface tension – a positive gradient – as this results in Marangoni convection radially inwards. Small differences in the concentrations of surface-active elements such as oxygen and sulphur can cause changes in the surface tension to temperature gradient in a weld pool and thus have a large effect on the weld penetration.

The Lorentz force during welding is an artefact of the interaction between the current flow in the weld pool and the magnetic field it induces. This force is proportional to the arc current squared and so is stronger at higher currents [6]. In addition to this, electrical resistivity in a metal is temperature dependent with cooler temperatures resulting in less resistance. In arc welding, the concentration of heat will reduce the further from the centre of the electric arc. As current flow favours cooler areas of less resistance, the hotter central region of the weld pool will become increasingly inefficient at conducting current, reducing the current density.

The difference in current densities created by the difference in resistance results in the magnetic field created by the current pushing the weld pool downwards. The force is weaker near the bottom of the weld pool and this creates a toroidal vortex, which results in significant heat transfer deeper into the weld pool.

Arc pressure is caused by the incompressibility of the welding arc plasma. Thus the momentum the arc transfers when it impacts the weld pool pushes the surface downward. An increase in arc pressure can cause an increasingly more concave surface of the weld pool [7]. In addition to the downward pressure from the welding arc, the shield gas also acts to perturb the weld pool but with considerably lower pressure [8].

The force from the Marangoni effect is often correctly labelled as the dominant force in weld pool dynamics, yet it is important to emphasise that it is not overwhelmingly dominant and, in fact, the electromagnetic force is particularly important at higher temperatures. Additional forces such as buoyancy – from the different densities between the hotter and colder areas of the weld pool also affect weld pool dynamics but at an order of magnitude less than the Marangoni effect [5].

TIG welding arc physics

TIG welding arcs are complex phenomena that are difficult to model accurately. Typically, electrons flow out of the electrode (cathode) and into the workpiece (anode) ionising the shielding gas to create a plasma, which is a mixture of approximately equal parts electrons and ionised shielding gas ions [9]. The electrons are emitted from the electrode through thermionic, thermo-field and field emission in addition to secondary emissions such as when highly energetic ions from the shielding gas collide with the electrode and as electron emissions from the anode [10].

The properties of the arc – particularly anode current density and heat flux to the workpiece, which determine the heat flow into the weld pool [11] – strongly affect the quality of the weld produced. The Lorentz Force acts to pinch the arc thus increasing its energy density and the arc pressure distorts the surface of the weld pool.

The flow of the cathode plasma jet along the surface of the weld pool leads to an aerodynamic drag force that pushes the surface of the weld pool radially outwards. These various effects have different reliance on the arc current thus modelling of TIG welding arcs is complex and several approximations are typically made [12] to [14]. Usually, local thermodynamic equilibrium (LTE) and a flat weld pool surface are assumed. However, high currents produce large arc pressures – resulting in concave weld pool surfaces – and welding arcs are not in LTE [2].

Deep penetration welding

To achieve deep penetration welding with TIG, the heat from the welding arc must penetrate far into the workpiece, creating a deep weld pool. The two prominent TIG-based techniques that achieve this are Keyhole TIG and Activated Flux TIG.

Figure 1: Ideal Marangoni convection for deep penetration welding.
Feasibility of deep penetration TIG welding

Keyhole TIG or K-TIG involves a small ‘keyhole’ punched through the work piece enabling the formation of a narrow cavity during welding which allows the heat from the welding arc to be distributed deep into the work piece. This keyhole remains open due to electromagnetically driven arc jets [15]. Standard TIG welding has an energy density of the order 107 W/m² [16]. Typically, welding processes involving energy densities of between 1 010 and 1 013 W/m² are required to achieve keyhole formation and stability using the recoil pressure – from the vaporising metal – to keep the keyhole open during welding [17]. Increasing energy densities further, to above 1 013 W/m², results in the work piece vapourising faster than the energy can be dissipated through it, thus welding is not possible.

K-TIG mitigates the traditionally insufficient energy densities of TIG based techniques by surrounding the tungsten electrode with a cooling shoulder, which passes water around it to restrict the high temperature area of the electrode to the tungsten tip. Combined with the magnetic ‘pinching’ effect in plasmas – a process whereby the flow of charged particles induces a magnetic field around themselves which in turn constricts the flow of the charged particles – the arc jet diameter is restricted and thus the energy density of the arc is increased [18]. When the arc pressure reaches a sufficient level, the surface tension of the weld pool can be overcome and a keyhole is formed [19].

Activated Flux TIG welding was invented in 1960 at the Paton Electric Welding Institute in Ukraine [20]. It involves the addition of surfactants to the surface of the work piece so that the Marangoni flow is radially inwards. Typically, the hotter regions in a molten metal will have a lower surface tension than the cooler regions. However, with the addition of a flux containing chalcogens such as oxygen, sulfur and selenium, this flow can be reversed. This is due to the increase in surface tension with temperature they cause within the weld pool. Typically, surface tension decreases with temperature but through the addition of chalcogens this is reversed and, as temperature drops off at 500 K/mm from the centre of the weld pool, there is a higher surface tension at the centre of the weld pool. This is illustrated in Figure 1, showing ideal Marangoni convection for deep penetration welding where surface tension is marked ⧫. This effect is particularly important when welding steel as it can have been found that if the concentration of sulphur or oxygen exceeds 50 ppm, the Marangoni flow will be radially inwards [8] – ideal for deep penetration welding.

The ‘Red Region’ of current

Using a thermal camera, the Red Region of current was first observed at The University of Sheffield, at welding currents above 300 A, significant surface instability began with vigorous fluctuations observed. Oscillating fluctuations of the weld pool surface is indicative of competing forces. Typically, arc pressure pushes the surface of the weld pool downwards and, in K-TIG, this effect is used to form the keyhole. Conversely, a characteristic of inwards Marangoni convection is a raising of the weld pool’s surface [21], thus there are documented effects that raise and lower the surface of the weld pool.

However, this is not a sufficient explanation for the fluctuations observed as the Marangoni convection depends on the temperature dependence of the surface tension of the work piece, meaning that temperature would decrease as the arc pressure pushes the surface of the weld pool away from the maximum in-arc temperature near the electrode tip [22].

This effect was first observed when welding with a VCie 500DHC, so to confirm the fluctuations in the weld pool are not an artefact of the VCie 500DHC welding machine, the Miller Dynasty 350 was also used in this study.

There is not an obvious explanation as to the origin of the ‘Red Region’ and as to why specifically 300 A triggers such vigorous effects. By understanding the ‘Red Region’ it could potentially be manipulated for deep penetration welding. The following experimental procedure will explain the first attempts to understand and quantify its effects by investigating the voltage, current and power used by the two aforementioned welding machines and their performance at high amperages.

Industry academia collaboration

The University of Sheffield and VCie have been involved in industry-academia collaboration since 2006. The chief focus of the collaboration has been knowledge transfer from technology research for the ATLAS detector at the CERN Large Hadron Collider [23]. Specifically, technology developed for the welding of the cooling system for the ATLAS upgrade has been used to develop VCie welding technology.

Experimental Procedure

The experiment involved comparing the efficacy of the welds produced by the Miller Dynasty 350 (Miller) and the VCie 500DHC without the DHC feature but with the InterPulse feature (Interpuls), and also to the VCie with the DHC and InterPulse features (DHC). Weld efficacy was accessed through investigating electrical measurements for the current produced by the machines compared to the current level the machines were set to. In addition to this, the power consumption of the machines was investigated by measuring the power drawn from the mains.

The welding was carried out on pieces of 22-inch OD, 0.5-inch wall thickness, 316 stainless steel tubing. The tubing was manipulated using a VCie Model W Assisted Hinge turntable. The welding torch was precisely positioned above the stainless steel tubing using a set of linear positioners to adjust the height and keep the arc gap at 3.0 mm for all of the machines. The experimental set-up is illustrated in Figure 2.

Welds were produced at 100 A, 150 A and 200 A for all three machines. These values were chosen to explore a broad range of higher current values. The current measurements were taken using a custom built shunt box which sampled the measurements as an analogue signal. To eliminate noise, a 5.0 Hz low-pass filter was applied to the data. This frequency was found to best isolate the signal from the background. The turntable controlled the welding speed and distance so that each weld was 5.76 cm long and welded at a speed of 35.9 cm/min.

The VCie DHC feature

The VCie 500DHC features a Dynamic Heat Control (DHC) mode which is designed to facilitate superior weld quality. The DHC mode alters the welding current profile to manipulate the heat input and improve weld quality. This is achieved by reducing the current once the weld pool has been formed and thus mediate the heat input to the workpiece.

Results and discussion

The current, voltage and power drawn from the mains were each measured three times for each machine at each current setting. The average values for each measurement are shown in Table 1. The current profile at 150 A for each machine is shown in Figure 3.

The current profiles were compared to the values of current produced by the Miller machine in use to synchronise the welding process.
that the machines were set to and the percentage deviation from the set value could then be determined. For instance, the average current level from the profiles in Figure 3 would be compared to 150 A. In determining the accuracy of the DHC between its stated and delivered current, its unique current profile was accounted for.

Figure 4 shows a comparison of the average percentage deviation over the three welding currents for each machine. It also shows the cumulative power used by each machine. This was calculated by finding the average power at each current level and then summing these values for each machine. The VBCie 500DHC with the DHC mode on boasts both the lowest cumulative power consumption and the lowest percentage deviation – the highest accuracy of all the configurations tested.

Conclusion
This comparison suggests both machines are capable of reasonable accuracy at higher currents. Furthermore, the current profiles on both machines can be identified and processed and thus any interesting activity in the ‘Red Region’ can be recognised. This preliminary investigation into the ‘Red Region’ lays the ground for future work. The next step would be to establish a computational model, which reflects the findings of this paper and a welding vision system. In addition to this, voltage measurements could be taken so that the power generated by the machines can be found and thus, the efficiency of the machines can be calculated.

A welding vision system is currently under development at The University of Sheffield as is the development of a voltage sensor for high welding currents.
